Abstract

The J wave, a deflection that follows the QRS complex of the surface ECG, is usually partially buried in the R wave in humans, appearing as a J point elevation. An early repolarization (ER) pattern characterized by J point elevation, slurring of the terminal part of the QRS and ST segment elevation has long been recognized and considered to be totally benign. Recent studies have presented evidence demonstrating that an ER pattern in inferior leads or infero-lateral leads is associated with increased risk for life-threatening arrhythmias, named early repolarization syndrome (ERS). ERS and Brugada syndrome (BrS) share similar ECG characteristics, clinical outcomes, risk factors as well as a common arrhythmic platform related to amplification of ifo-mediated J waves. Although BrS and early repolarization syndrome (ERS) differ with respect to the magnitude and lead location of abnormal J wave manifestation, they can be considered to represent a continuous spectrum of phenotypic expression, termed J wave syndromes. ERS has been proposed to be divided into three subtypes: Type 1, displaying an ER pattern predominantly in the lateral precordial leads, is prevalent among healthy male athletes and rarely seen in VF survivors; Type 2, displaying an ER pattern predominantly in the inferior or infero-lateral leads, is associated with a higher level of risk; whereas Type 3, displaying an ER pattern globally in the inferior, lateral and right precordial leads, is associated with the highest level of risk for development of malignant arrhythmias and is often associated with VF storms.

Keywords
Cardiac arrhythmias; Sudden cardiac death; Sudden cardiac arrest; Transient outward current; J point elevation; Early repolarization syndrome; Brugada syndrome; Idiopathic Ventricular fibrillation; Hypothermia; STEMI

The J wave is a deflection that follows the QRS complex on the surface electrocardiogram (ECG). When partially buried in the R wave, the J wave appears as a J point elevation and may be accompanied by an ST segment elevation, an ECG feature referred to as an early repolarization (ER) pattern. Recent studies have provided evidence in support of an
association of ER pattern with life-threatening arrhythmias, designated as early repolarization syndrome (ERS) or Brugada syndrome (BrS) based on the region of the heart responsible for the arrhythmogenic substrate. Although BrS and ERS differ with respect to the magnitude and lead location of abnormal J wave manifestation, they are thought to represent a continuous spectrum of phenotypic expression termed J wave syndromes.\(^1\)

The early repolarization pattern, consisting of a distinct J wave or J point elevation, a notch or slur of the terminal part of the QRS and an ST segment elevation, is predominantly found in healthy young males and has traditionally been viewed as benign.\(^2,3\) Our observation in 2000 that an ER pattern in the canine coronary-perfused wedge preparation can easily convert to one in which phase 2 reentry gives rise to polymorphic ventricular tachycardia/ventricular fibrillation (VT/VF), prompted the suggestion that ER may in some cases predispose to malignant arrhythmias in the clinic.\(^1,4,5\) A number of case reports and experimental studies have suggested a critical role for the J wave in the pathogenesis of idiopathic ventricular fibrillation (IVF).\(^6-14\) A definitive association between ER and IVF was presented in the form of two studies published in the New England Journal of Medicine in 2008.\(^15,16\) These were followed by another study from Viskin and co-workers\(^17\) that same year and two large population association studies in 2009 and 2010.\(^18,19\)

Based on the available clinical data, we recently suggested a classification scheme that attempts to risk stratify patients with ER.\(^1\) An ER pattern manifest exclusively in the lateral precordial leads was designated as Type 1; this form is prevalent among healthy male athletes and is thought to be associated with a relatively low level of risk for arrhythmic events. ER pattern in the inferior or infero-lateral leads was designated as Type 2; this form is thought to be associated with a moderate level of risk. Finally, an ER pattern appearing globally in the inferior, lateral and right precordial leads was labeled Type 3; this form is associated with the highest level of risk and in some cases has been associated with electrical storms.\(^1\) BrS represents a fourth variant in which ER is limited to the right precordial leads.

**Ionic and Cellular Basis for the J wave and Associated Arrhythmogenesis**

Transmural differences in the early phases of the action potential have long been recognized as the basis for inscription of the electrocardiographic J wave.\(^20,21\) The ventricular epicardial action potential, particularly in the right ventricle, displays a prominent transient outward current (I\(_{to}\))-mediated notch or spike and dome morphology. The presence of a prominent I\(_{to}\)-mediated action potential notch in ventricular epicardium but not endocardium produces a transmural voltage gradient that registers as a J wave or J point elevation on the ECG. Direct evidence in support of this hypothesis was first obtained in arterially-perfused canine ventricular wedge preparations\(^7\) as illustrated in Figure 1. Factors that influence I\(_{to}\) kinetics or ventricular activation sequence can modify the manifestation of the J wave on the ECG. Whether reduced by I\(_{to}\) blockers such as 4-aminopyridine or premature activation or augmented by exposure to hypothermia, changes in the magnitude of the epicardial action potential notch parallel those of the J wave.\(^22,23\)

Augmentation of net repolarizing current, secondary to a decrease of inward currents or an increase of outward current, accentuates the notch leading to augmentation of the J wave or appearance of ST segment elevation. A further increase in net repolarizing current can result in partial or complete loss of the action potential dome, leading to a transmural voltage gradient that manifests as accentuation of the J wave or an ST segment elevation.\(^5,22,23\) In regions of the myocardium exhibiting a prominent I\(_{to}\) such as the right ventricular epicardium, marked accentuation of the action potential notch and a coved-type ST segment elevation diagnostic of BrS (Fig. 2B). A further outward shift of the currents active during
the early phase of the action potential can lead to loss of the action potential dome, thus creating a dispersion of repolarization between epicardium and endocardium as well as within epicardium, between the region where the dome is lost and regions at which it is maintained (Fig. 2C). Sodium channel blockers like procainamide, pilsicainide, propafenone, flecainide and disopyramide cause a further outward shift of current flowing during the early phases of the action potential and therefore effective in inducing or unmasking ST segment elevation in patients with concealed J-wave syndromes. Sodium channel blockers like quinidine, which also inhibits \( I_{\text{to}} \), reduce the magnitude of the J wave and normalize ST segment elevation. Loss of the action potential dome is usually heterogeneous, resulting in marked abbreviation of action potential at some sites but not others. The dome can then propagate from regions where it is maintained to regions where it is lost, giving rise to a very closely coupled extrasystole via phase 2 reentry (Fig. 2D). The phase 2 reentrant beat can then initiate a polymorphic ventricular tachycardia (VT) or ventricular fibrillation (Figs. 2E and F).

The outward shift of current may extend beyond the action potential notch and thus lead to depression of the dome in addition to accentuating the J wave. Activation of the ATP-sensitive potassium current (\( I_{\text{K-ATP}} \)) or depression of inward calcium channel current (\( I_{\text{Ca}} \)) can effect such a change (Figs. 3A and B). This is more likely to manifest in the ECG as an ER pattern consisting of a J point elevation, slurring of the terminal part of the QRS and mild ST segment elevation. The ER pattern can facilitate loss of the dome due to other factors and thus lead to the development of ST segment elevation, phase 2 reentry and VT/VF. (Fig. 3C and D).

**Clinical manifestations of J wave syndromes**

In both ERS and BrS, the manifestation of the J wave or ER is dynamic, with the most prominent ECG changes appearing just before the onset of VT/VF. Other ECG characteristics of ERS also closely match those of BrS, including the presence of accentuated J waves, pause and bradycardia-dependence, short coupled extrasystole-induced polymorphic VT/VF. Suppression of the ECG features by isoproterenol or pacing in ER patients further supports the notion that they share common underlying electrophysiologic abnormalities with BrS patients. However, salient diagnostic features of BrS such as provocation by sodium channel blockers or positive signal averaged ECG are rarely observed in these IVF patients.

BrS has been associated with mutations in ten different genes. Over 300 mutations in \( SCN5A \) (\( \alpha_1 \), BrS1) have been reported in 11–28% of BrS probands. Mutations in \( CACNA1C \) (\( \alpha_1 \), BrS1), \( CACNB2b \) (\( \alpha_2 \delta \), BrS4) and \( CACNA2D1 \) (\( \alpha_2 \), BrS9) are found in approximately 13% of probands. Mutations in glycerol-3-phosphate dehydrogenase 1-like enzyme gene (\( GPD1L \), BrS2), \( SCN1B \) (\( \beta_1 \)-subunit of \( Na \) channel, BrS5), \( KCNE3 \) (MiRP2; BrS6), \( SCN3B \) (\( \beta_3 \)-subunit of \( Na \) channel, BrS7), \( KCNJ8 \) (BrS8) and \( KCND3 \) (BrS10) are more rare. Mutations in these genes lead to loss of function in \( I_{\text{Na}} \) and \( I_{\text{Ca}} \), as well as to a gain of function in \( I_{\text{to}} \) or \( I_{\text{K-ATP}} \).

The genetic basis for ER is slowly coming into better focus. Consistent with the findings that \( I_{\text{K-ATP}} \) activation can generate an ER pattern in canine ventricular wedge preparations, a rare variant in \( KCNJ8 \), responsible for the pore forming subunit of the \( I_{\text{K-ATP}} \) channel, has recently been reported in a patient with ERS; expression studies are not available as yet. Recent studies from our group have recently identified loss of function mutations in the \( \alpha_1 \) and \( \beta_2 \) and \( \alpha_2 \delta \) subunits of the cardiac L-type calcium channel (\( CACNA1C, CACNB2, \) and \( CACNA2D1 \)) in patients with ERS.
As in most cases of BrS, bradycardia accentuates ST segment elevation, and tachycardia tends to normalize the ST segment in ERS. VF often occurs near midnight or in the early morning hours when heart rate is slower and parasympathetic tone is augmented.\textsuperscript{10, 44}

In BrS, the manifestation of spontaneous ST segment elevation has been associated with a higher risk for development of arrhythmic events. Risk stratification of asymptomatic patients remains a challenge. In the case of ERS, it is clear that the vast majority of individuals with ER are at no or minimal risk for arrhythmic events and sudden cardiac arrest. Our challenge moving forward is to develop better risk stratification strategies and effective treatments for the J wave syndromes.

Our working hypothesis is that an outward shift in repolarizing current due to a decrease in sodium or calcium channel currents or an increase in \( I_{to} \), \( I_{K_{ATP}} \), \( I_{K_{ACH}} \), or other outward currents gives rise to the J wave syndromes (Fig. 4). The particular phenotype depends on what part of the heart is principally affected and which ion channels are involved. We view the J wave syndromes as a spectrum of disorders that involve accentuation of the epicardial action potential notch in different regions of heart, leading to the development of prominent J waves that predispose to the development of VT/VF.

In the case of BrS, the appearance of prominent J waves is limited to the leads facing the right ventricular outflow tract where \( I_{to} \) is most prominent. The more prominent \( I_{to} \) in right ventricular epicardium provides for an outward shift in the balance of current which promotes the appearance of the J wave in this region of the ventricular myocardium. In the case of ERS, the appearance of prominent J waves may be limited to other regions of the ventricular myocardium because of the presence of heterogeneities in the distribution of other currents such as \( I_{K_{ATP}} \).

Risk stratification

While it is clear that the vast majority of individuals presenting with an ER pattern in the ECG are at no or minimal risk, the challenge currently facing the cardiology community is how to distinguish ER patterns in healthy individuals from those who carry significant arrhythmic risk. In addition to the classification scheme proposed\textsuperscript{1}, available data suggest that a J point elevation of \( >0.2 \) mV\textsuperscript{18}, accompanying short QTc intervals\textsuperscript{45} or distinct J waves \textsuperscript{46} should raise a red flag. A recent study by Tikkanen and coworkers reports that a rapidly ascending ST segment after the J-point, the dominant ST pattern found in healthy athletes, seems to be a benign variant of ER, whereas a horizontal or descending ST segment elevation is associated with an increased risk for arrhythmic death.\textsuperscript{47}

Figure 1.
Hypothermia-induced J wave. Each panel shows transmembrane action potentials from the epicardial and endocardial regions of an arterially perfused canine left ventricular wedge and a transmural ECG simultaneously recorded. A: The relatively small action potential notch in epicardium but not in endocardium is associated with an elevated J-point at the R-ST junction (arrow) at 36°C. D: A decrease in the temperature of the perfusate to 29°C results in an increase in the amplitude and width of the action potential notch in epicardium but not endocardium, leading to the development of a transmural voltage gradient that manifests as a prominent J wave on the ECG (arrow). (Modified from 7, with permission)
Figure 2.
Cellular basis for electrocardiographic and arrhythmic manifestation of BrS. Each panel shows transmembrane action potentials from one endocardial (top) and two epicardial sites together with a transmural ECG recorded from a canine coronary-perfused right ventricular wedge preparation. A: Control (Basic cycle length (BCL) 400 msec). B: Combined sodium and calcium channel block with terfenadine (5 µM) accentuates the epicardial action potential notch creating a transmural voltage gradient that manifests as a ST segment elevation or exaggerated J wave in the ECG. C: Continued exposure to terfenadine results in all-or-none repolarization at the end of phase 1 at some epicardial sites but not others, creating a local epicardial dispersion of repolarization (EDR) as well as a transmural dispersion of repolarization (TDR). D: Phase 2 reentry occurs when the epicardial action potential dome propagates from a site where it is maintained to regions where it has been lost giving rise to a closely coupled extrasystole. E: Extrastimulus (S1–S2 = 250 msec) applied to epicardium triggers a polymorphic VT. F: Phase 2 reentrant extrasystole triggers a brief episode of polymorphic VT. (Modified from reference 48, with permission)
Figure 3.
Cellular basis for the early repolarization syndrome. 

A: Surface ECG (lead V5) recorded from a 17-year-old healthy African American male. Note the presence of a small J wave and marked ST segment elevation.

B: Simultaneous recording of transmembrane action potentials from epicardial (Epi) and endocardial (Endo) regions and a transmural ECG in an isolated arterially perfused canine left ventricular wedge. A J wave in the transmural ECG is manifest due to the presence of an action potential notch in epicardium but not endocardium. Pinacidil (2 µM), an ATP-sensitive potassium channel opener, causes depression of the action potential dome in epicardium, resulting in ST segment elevation in the ECG resembling the early repolarization syndrome.
